#### **Abstract**

Releasing person-specific data in its most specific state poses a threat to individual privacy. This paper presents a practical and efficient algorithm for determining a generalized version of data that masks sensitive information and remains useful for modelling classification. The generalization of data is implemented by specializing or detailing the level of information in a top-down manner until a minimum privacy requirement is violated. This top-down specialization is natural and efficient for handling both categorical and continuous attributes. Our approach exploits the fact that data usually contains redundant structures for classification. While generalization may eliminate some structures, other structures emerge to help. Our results show that quality of classification can be preserved even for highly restrictive privacy requirements. This work has great applicability to both public and private sectors that share information for mutual benefits and productivity.

## 1. Introduction

Data sharing in today globally networked systems poses a threat to individual privacy and organizational confidentiality. An example in Samarati [9] shows that linking medication records with a voter list can uniquely identify a person's name and her medical information. In response, new privacy acts and legislations are recently enforced in many countries. In 2001, Canada launched the *Personal Information Protection and Electronic Document Act* [11] to protect a wide spectrum of information, e.g., age, race, income, evaluations, and even intentions to acquire goods or services. This information spans a considerable portion of many databases. Government agencies and companies have to revise their systems and practices to fully comply with this act in three years.

Consider a table T about patient's information on Diagnosis, Zip code, Birthdate, and Sex. If a description on (Zip

code, Birthdate, Sex) is so specific that not many people match it, releasing the table will lead to linking a unique or a small number of individuals with the information on Diagnosis. Even if sensitive attributes like Diagnosis are not contained in the table to be released, but contained in an external source, they can be linked to identifying attributes (Zip code, Birthdate, Sex) [9].

Suppose that Zip code, Birthdate, Sex, and Diagnosis must be released, say, to some health research institute for research purpose. We can still protect privacy by replacing specific descriptions with less specific but semantically consistent descriptions. This operation is called *generalization*. For example, by replacing Birthdate with Birthyear (or replacing a specific age value with an interval), more records will match a description on (Zip code, Birthyear, and Sex), making the description less identifying. The premise is that a table T contains only a subset of all individuals. If a description is less specific, more individuals, both within and outside T, will match it, making it difficult to tell whether a matched individual actually has the diagnosis as recorded in T.

Protecting privacy is one side of the story. Another side of the story is making the released data useful to data analysis. Can the two goals be achieved at the same time? In this paper, we like to answer this question for using the data for classification. Our insight is that these two goals are really dealing with two types of information: The privacy goal requires to mask sensitive information, usually *specific* descriptions that identify individuals, whereas the classification goal requires to extract *general* structures that capture trends and patterns. If generalization is performed "carefully", identifying information can be masked while still preserving the trends and patterns for classification. Our experimental results support this insight.

**Example 1** [The running example] Consider the data in Table 1 and taxonomy trees in Figure 1. Originally, the table has 34 records. We have removed irrelevant attributes and now each row represents one or more original records. The

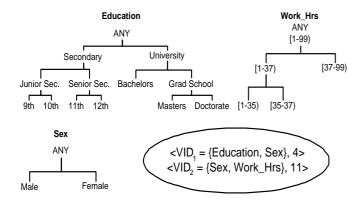

Figure 1. Taxonomy trees and VIDs

Class column contains the class frequency of the records represented, Y for income >50K and N for otherwise. To make "female doctor" less unique, we can generalize Masters and Doctorate to Grad School. As a result, "she" becomes less distinguishable by being one of the four inside and many more outside the table who are female and have graduate school degrees. As far as classification is concerned, no information is lost in this generalization because Class does not depend on the distinction of Masters and Doctorate. ■

In this paper, the privacy goal is specified by the anonymity on a combination of attributes called a virtual identifier, where each description on a virtual identifier is required to be shared by some minimum number of records in the table. A generalization taxonomy tree is specified for each categorical attribute in a virtual identifier. We present a Top-Down Specialization (TDS) approach to generalize a table to satisfy the anonymity requirement while preserving its usefulness to classification. TDS generalizes the table by specializing it iteratively starting from the most general state. At each step, a general (i.e. parent) value is specialized into a specific (i.e. child) value for a categorical attribute, or an interval is split into two sub-intervals for a continuous attribute. This process is repeated until further specialization leads to a violation of the anonymity requirement.

A number of features make TDS practical:

- Information and privacy-guided specialization. Both
  information and privacy are considered in selecting
  the specialization at each step. Experiments show that
  classification based on the generalized data yields an
  accuracy comparable to classification based on the unmodified data, even for a very restrictive anonymity
  requirement.
- Handling both categorical and continuous attributes.

Education	Sex	Work_Hrs	Class	# of Recs.
9th	M	30	0Y3N	3
10th	M	32	0Y4N	4
11th	M	35	2Y3N	5
12th	F	37	3Y1N	4
Bachelors	F	42	4Y2N	6
Bachelors	F	44	4Y0N	4
Masters	M	44	4Y0N	4
Masters	F	44	3Y0N	3
Doctorate	F	44	1Y0N	1
			Total:	34

Table 1. (Compressed) table

This method does not require a priori discretized taxonomy tree for a continuous attribute, but dynamically obtains one in the top-down specialization process. TDS is especially efficient for handling continuous attributes in that a small number of intervals is obtained via a small number of specializations.

- Handling multiple virtual identifiers. Often, there are
  more than one virtual identifier to identify individuals.
  Treating all virtual identifiers as a single united virtual
  identifier leads to unnecessary generalization and loss
  of data quality. Our method allows specialization on
  multiple virtual identifiers to avoid unnecessary generalization.
- Scalable computation. At each iteration, a key operation is updating some goodness metric of affected candidate specializations. In general, this requires accessing data records. Our method incrementally maintains some "count statistics" to eliminate the expensive data access. Simple but effective data structures are proposed for this purpose. Our method deals with the compressed table, which is usually smaller than the original table, and is amendable to disk-resident data.
- Anytime solution. The top-down approach provides a natural tree-growing procedure that allows the user to step through each specialization to determine a desired trade-off between privacy and accuracy. The user may stop at any time and have a table satisfying the anonymity requirement. This property is not shared by the bottom-up generalization that starts with the most precise state.

We review related work in Section 2, define the problem in Section 3, define the goodness criterion of specialization in Section 4, present the top-down specialization approach in Section 5, evaluate this approach in Section 6. Finally, we conclude the paper.

## 2. Related Work

Many techniques have been proposed previously to preserve privacy, but most are not intended for classification. For example, Kim et al. [7] and Fuller [3] show that some simple statistical information, like means and correlations, can be preserved by adding noise and swapping values. Recently, this technique was studied in data mining for classification [1]. In these works, privacy was measured by how closely the original values of a masked attribute can be estimated, which is very different from the notion of anonymity that quantifies how uniquely an individual can be linked with sensitive information.

The concept of anonymity was proposed in [2]. Bottom-up generalization was used to achieve anonymity in Datafly system [10] and  $\mu$ -Argus system [5]. These works assumed a single virtual identifier that includes all attributes that could potentially be used to link the data to an external source. In our work, the linking can be either to an external source or among the attributes in the table itself. In the latter case all virtual identifiers may be known at the time of problem specification. They did not consider classification or a specific use of data, and simple heuristics were used, such as selecting the attribute having most number of distinct values [10] or values not having k occurrences [5] to generalize. Such heuristics did not address the quality for classification.

Iyengar [6] presented the anonymity problem for classification, and proposed a genetic algorithm solution. The idea is encoding each state of generalization as a "chromosome" and encoding data distortion into the fitness function, and employing the genetic evolution to converge to the fittest chromosome. Wang et al. [12] recently presented an effective bottom up approach, but it can only generalize categorical attributes. Unlike the *random* genetic evolution and the bottom-up generalization, our approach produces a progressive generalization process which the user can step through to determine a desired trade-off of privacy and accuracy. We handle both categorical and continuous attributes, and multiple virtual identifiers. We focus on scalability, in addition to data quality. Iyengar reported 18 hours to transform 30K records. Our algorithm took only 7 seconds to produce a comparable accuracy on the same data. For large databases, Iyengar suggested running his algorithm on a sample. However, a small sampling error could mean failed protection on the entire data.

#### 3. Problem Definition

A data provider wants to release a person-specific table  $T(D_1, \ldots, D_m, Class)$  to the public for modelling the class label Class. Each  $D_i$  is either a categorical or a continuous attribute. A record has the form  $\langle v_1, \ldots, v_m, cls \rangle$ ,

where  $v_i$  is a domain value for  $D_i$  and cls is a class for Class. att(v) denotes the attribute of a value v. The data provider also wants to protect against linking an individual to sensitive information either within or outside T through some identifying attributes, called a *virtual identifier* or simply VID. A sensitive linking occurs if some value of the virtual identifier is shared by only a "small" number of records in T. This requirement is formally defined below.

**Definition 1 (Anonymity requirement)** Consider p virtual identifiers  $VID_1, \ldots, VID_p$  on T.  $a(vid_i)$  denotes the number of data records in T that share the value  $vid_i$  on  $VID_i$ . The anonymity of  $VID_i$ , denoted  $A(VID_i)$ , is the smallest  $a(vid_i)$  for any value  $vid_i$  on  $VID_i$ . A table T satisfies the anonymity requirement  $\{ < VID_1, k_1 >, \ldots, < VID_p, k_p > \}$  if  $A(VID_i) \ge k_i$  for  $1 \le i \le p$ , where  $k_i$  is the anonymity threshold on  $VID_i$  specified by the data provider. ■

We assume that  $VID_j$  is not a subset of  $VID_i$ ,  $j \neq i$ , otherwise,  $VID_j$  can be removed from the requirement.

**Example 2** Consider Table 1. To protect against sensitive linking through  $\{Education, Sex\}$ , we specify  $\langle VID_1 = \{Education, Sex\}, 4\rangle$ , that is, every existing vid in T must be shared by at least 4 records in T. The following vids violate this requirement:  $\langle 9th, M \rangle$ ,  $\langle Masters, F \rangle$ ,  $\langle Doctorate, F \rangle$ . To protect against linking through  $\{Sex, Work\_Hrs\}$  as well, the anonymity requirement could include the two VIDs such as in Figure 1.  $\blacksquare$ 

To generalize T to satisfy the anonymity requirement, a  $taxonomy\ tree$  is specified for each categorical attribute in  $\cup VID_i$ , by either the data provider or the data recipient. A leaf node represents a domain value and a parent node represents a less specific value. For a continuous attribute in  $\cup VID_i$ , our algorithm dynamically grows a taxonomy tree at runtime, where each node represents an interval, and each non-leaf node has two child nodes representing some "optimal" binary split of the parent interval. More details on this will be discussed in Section 4. Figure 1 shows a dynamically grown taxonomy tree for  $Work\_Hrs$ .

Let child(v) be the set of child values of v in the taxonomy tree. A table T can be generalized by a sequence of generalizations starting from data records. A *generalization*, written  $child(v) \rightarrow v$ , replaces child values in child(v) with their parent value v. To ensure that the result is easy to understand, prior to the generalization, all values below the values in child(v) should be generalized to those in child(v) first, so that a descendant value and an ancestor value do not coexist in the generalized data.

Alternatively, T can be generalized by a sequence of specializations starting from the most general state in which each attribute has the top most value of its taxonomy tree.

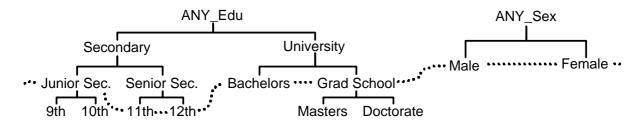

Figure 2. Example 3: A solution cut for  $VID_1 = \{Education, Sex\}$ 

A specialization, written  $v \to child(v)$ , replaces the parent value v with a child value in child(v) that generalizes the domain value in a record. A specialization is valid (with respect to T) if T satisfies the anonymity requirement after the specialization. A specialization is beneficial (with respect to T) if more than one class is involved in the records containing v. A specialization is performed only if it is both valid and beneficial.

#### **Definition 2 (Anonymity for Classification)** Given

a table T, an anonymity requirement  $\{ \langle VID_1, k_1 \rangle \}$  $,\ldots,\langle VID_p,k_p\rangle\}$ , and a taxonomy tree for each categorical attribute contained in  $\cup VID_i$ , generalize T on the attributes  $\cup VID_i$  to satisfy the anonymity requirement while preserving as much information as possible for classification. ■

A generalized T can be viewed as a "cut" through the taxonomy tree of each attribute in  $\cup VID_i$ . A *cut* of a tree is a subset of values in the tree that contains exactly one value on each root-to-leaf path. A solution cut is  $\cup Cut_i$ , where  $Cut_i$  is a cut of the taxonomy tree of an attribute in  $\cup VID_i$ , such that the generalized T represented by  $\cup Cut_i$ satisfies the anonymity requirement. We are interested in a solution cut that maximally preserves the information for classification.

**Example 3** Continue with Example 2. Figure 2 shows a solution cut, indicated by the dashed curve. This solution cut is the lowest in the sense that any specialization on Junior Sec. or Grad School would violate the anonymity requirement, i.e., is invalid. Also, specialization on Junior Sec. or Grad School is non-beneficial since none of them specializes data records in different classes.

#### 4. Search Criteria

Our top-down specialization starts from the top most solution cut and pushes down the solution cut iteratively by specializing some value in the current solution cut until violating the anonymity requirement. Each specialization tends to increase information and decrease anonymity because records are more distinguishable by specific values. The key is selecting a specialization at each step with both impacts considered. In this section, we consider a goodness metric for a single specialization.

Consider a specialization  $v \rightarrow child(v)$ . Let  $R_v$  denote the set of records generalized to the value v, and let  $R_c$  denote the set of records generalized to a child value cin child(v) after specializing v. Let |x| be the number elements in a set x.  $|R_v| = \sum_c |R_c|$ , where  $c \in child(v)$ . The effect of specializing v is summarized by the "information gain", denoted InfoGain(v), and the "anonymity loss", denoted AnonyLoss(v). To heuristically maximize the information of the generalized data for achieving a given anonymity, we favor the specialization on v that has the maximum information gain for each unit of anonymity loss:

$$Score(v) = \begin{cases} \frac{InfoGain(v)}{AnonyLoss(v)} & \text{if } AnonyLoss(v) \neq 0 \\ InfoGain(v) & \text{otherwise} \end{cases}$$

$$InfoGain(v): \text{ defined as}$$

$$InfoGain(v) = I(R_v) - \sum_c \frac{|R_c|}{|R_v|} I(R_c)$$

$$\text{where } I(R_x) \text{ is the } entropy \text{ of } R_x \text{ [8]:}$$

$$I(R_x) = -\sum_{cls} \frac{freq(R_x, cls)}{|R_x|} \times log_2 \frac{freq(R_x, cls)}{|R_x|}$$

$$freq(R_x, cls) \text{ is the number of data records in } R_x \text{ is } log_2 \frac{freq(R_x, cls)}{|R_x|}$$

$$InfoGain(v) = I(R_v) - \sum_c \frac{|R_c|}{|R_c|} I(R_c)$$

$$I(R_x) = -\sum_{cls} \frac{freq(R_x, cls)}{|R_x|} \times log_2 \frac{freq(R_x, cls)}{|R_x|}$$

 $freq(R_x, cls)$  is the number of data records in  $R_x$  having the class cls. Intuitively,  $I(R_x)$  measures the "mix" of classes for the data records in  $R_x$ . The two terms in InfoGain(v) are the mix of classes before and after specializing v. A good specialization will reduce the mix of classes, i.e., have a large InfoGain(v). Note that InfoGain(v) is non-negative [8].

**AnonyLoss(v)**: defined as

 $AnonyLoss(v) = avg\{A(VID_i) - A_v(VID_i)\},\$ where  $A(VID_j)$  and  $A_v(VID_j)$  represents the anonymity before and after specializing v.  $A(VID_j) - A_v(VID_j)$ is the loss of anonymity of  $VID_j$ , and  $avg\{A(VID_i)$  - $A_v(VID_i)$  is the average loss of all  $VID_i$  that contain the attribute of v.

Example 4 The specialization on ANY\_Edu refines the 34 records into 16 records for Secondary and 18 records for *University.* The calculation of  $Score(ANY\_Edu)$  is shown below.

For a continuous attribute, the specialization of an interval refers to the optimal binary split of the interval that maximizes the information gain. We use information gain, instead of Score, to determine the split of an interval because anonymity is irrelevant to finding a split good for classification. This is similar to the situation that the taxonomy tree of a categorical attribute is specified independently of the anonymity issue.

**Example 5** For the continuous attribute *Work\_Hrs*, the top most value is the full range interval of domain values, [1-99). To determine the split point of [1-99), we evaluate the information gain for the five possible split points for the values 30, 32, 35, 37, 42, and 44. The following is the calculation for the split point at 37:

```
\begin{split} InfoGain(37) &= I(R_{[1-99)}) - (\frac{12}{34} \times I(R_{[1-37)}) + \frac{22}{34} \times I(R_{[37-99)})) \\ &= 0.9597 - (\frac{12}{34} \times 0.6500 + \frac{22}{34} \times 0.5746) = 0.3584. \end{split}
```

As InfoGain(37) is highest, we grow the taxonomy tree for  $Work\_Hrs$  by adding two child intervals, [1-37) and [37-99), under the interval [1-99).

The next example shows that InfoGain alone may lead to a quick violation of the anonymity requirement, thereby, prohibiting specializing data to a lower granularity.

**Example 6** Consider Table 2, an anonymity requirement  $\langle VID = \{Education, Sex, Work\_Hrs\}, 4 \rangle$ , and specializations:

```
ANY\_Edu \rightarrow \{8th, 9th, 10th\},\ ANY\_Sex \rightarrow \{M, F\}, \text{ and } [1-99) \rightarrow \{[1-40], [40-99]\}.
```

The class frequency for the specialized values is:

Education: 0Y4N (8th), 0Y12N (9th), 20Y4N (10th)

Sex: 20Y6N (M), 0Y14N (F)

Work\_Hrs: 0Y12N ([1-40)), 20Y8N ([40-99))

Specializing *Education* best separates the classes, so is chosen by InfoGain. After that, the other specializations become invalid. Now, the two classes of the top 24 records become indistinguishable because they are all generalized into <10th,  $ANY\_Sex$ , [1-99)>.

In contrast, the *Score* criterion will first specialize *Sex* because of the highest *Score* due to a small *AnonyLoss*. Subsequently, specializing *Education* becomes invalid, and the next specialization is on *Work\_Hrs*. The final generalized table is shown in Table 3 where the information for distinguishing the two classes is preserved. ■

Education	Sex	Work_Hrs	Class	# of Recs.
10th	M	40	20Y0N	20
10th	M	30	0Y4N	4
9th	M	30	0Y2N	2
9th	F	30	0Y4N	4
9th	F	40	0Y6N	6
8th	F	30	0Y2N	2
8th	F	40	0Y2N	2
			Total:	40

Table 2. (Compressed) table for Example 6

Education	Sex	Work_Hrs	Class	# of Recs.
ANY_Edu	M	[40-99)	20Y0N	20
ANY_Edu	M	[1-40)	0Y6N	6
ANY_Edu	F	[40-99)	0Y8N	8
ANY_Edu	F	[1-40)	0Y6N	6

Table 3. Generalized table by Score for Example 6

## 5. Top-Down Specialization

## 5.1. The Algorithm

We present our algorithm,  $Top\text{-}Down\ Specialization\ (TDS)$ . In a preprocessing step, we compress the given table by removing all attributes not in  $\cup VID_j$  and collapsing duplicates into a single row with the Class column storing the class frequency as in Table 1. The compressed table is typically much smaller than the original table. Below, the term "data records" refers to data records in this compressed form. To focus on main ideas, we assume that the compressed table fits in the memory. In Section 5.5, we will discuss the modification needed if the compressed table does not fit in the memory.

Table 4 summarizes the conceptual algorithm. Initially,  $Cut_i$  contains only the top most value for its attribute. The valid, beneficial specializations in  $\cup Cut_i$  form the set of candidates to be performed next. At each iteration, we find the candidate of the highest Score, denoted Best (Line 5), apply Best to T and update  $\cup Cut_i$  (Line 6), and update Score and validity of the candidates in  $\cup Cut_i$  (Line 7). The algorithm terminates when there is no more candidate in  $\cup Cut_i$ , in which case it returns the generalized table together with  $\cup Cut_i$ .

**Example 7** Consider the anonymity requirement:

```
\{ \langle VID_1 = \{ Education, Sex \}, 4 \rangle, \\ \langle VID_2 = \{ Sex, Work\_Hrs \}, 11 \rangle \}.
```

Initially, all data records in Table 1 are generalized to *<ANY\_Edu*, *ANY\_Sex*, [1-99)>,

 $\cup Cut_i = \{ANY\_Edu, ANY\_Sex, [1-99)\}.$ 

All specializations in  $\cup Cut_i$  are candidates. To find the best specialization, we need to compute  $Score(ANY\_Edu)$ ,  $Score(ANY\_Sex)$ , and Score([1-99)).

Algorithm TDS 2 Initialize every value in T to the top most value. 3 Initialize  $Cut_i$  to include the top most value. 4 while some  $x \in \bigcup Cut_i$  is valid and beneficial do 5 Find the Best specialization from  $\cup Cut_i$ . Perform Best on T and update  $\cup Cut_i$ . 6 Update Score(x) and validity for  $x \in \cup Cut_i$ . 7 8 end while **return** Generalized T and  $\cup Cut_i$ .

Table 4. Top-Down Specialization (TDS)

The algorithm in Table 4 makes no claim on efficiency. In a straightforward method, Line 6 and 7 require scanning all data records and recomputing Score for all candidates in  $\cup Cut_i$ . Obviously, this is not scalable. The key to the efficiency of our algorithm is directly accessing the data records to be specialized, and updating Score based on some statistics maintained for candidates in  $\cup Cut_i$ , instead of accessing data records. In the rest of this section, we explain our scalable implementation and data structures in details.

## 5.2. Find the Best Specialization

This step makes use of computed InfoGain(x) and  $A_x(VID_j)$  for all candidates x in  $\cup Cut_i$  and computed  $A(VID_j)$  for each  $VID_j$ . Before the first iteration, such information is computed in an initialization step for every top most value. For each subsequent iteration, such information comes from the update in the previous iteration (Line 7). Finding the best specialization Best involves at most  $|\cup Cut_i|$  computations of Score without accessing data records. Updating InfoGain(x) and  $A_x(VID_j)$  will be considered in Section 5.4.

## 5.3. Perform the Best Specialization

First, we replace Best with child(Best) in  $\cup Cut_i$ . Then, we need to retrieve  $R_{Best}$ , the set of data records generalized to Best, to tell the child value in child(Best) for individual data records. We first present a data structure,  $Taxonomy\ Indexed\ PartitionS\ (TIPS)$ , to facilitate this operation. This data structure is also crucial for updating InfoGain(x) and  $A_x(VID_j)$  for candidates x. The general idea is to group data records according to their generalized records on  $\cup VID_j$ .

**Definition 3 (TIPS)** TIPS is a tree structure with each node representing a generalized record over  $\cup VID_i$ , and each

child node representing a specialization of the parent node on exactly one attribute. Stored with each leaf node is the set of (compressed) data records having the same generalized record, called a *leaf partition*. For each x in  $\cup Cut_i$ ,  $P_x$  denotes a leaf partition whose generalized record contains x, and  $Link_x$  denotes the link of all  $P_x$ , with the head of  $Link_x$  stored with x.

At any time, the generalized data is represented by the leaf partitions of TIPS, but the original data records remain unchanged.  $Link_x$  provides a direct access to  $R_x$ , the set of data records generalized to the value x. Initially, TIPS has only one leaf partition containing all data records, generalized to the top most value on every attribute in  $\cup VID_j$ . In each iteration, we perform the best specialization Best by refining the leaf partitions on  $Link_{Best}$ .

**Update TIPS**. We refine each leaf partition  $P_{Best}$  found on  $Link_{Best}$  as follows. For each value c in child(Best), a child partition  $P_c$  is created under  $P_{Best}$ , and data records in  $P_{Best}$  are split among the child partitions:  $P_c$  contains a data record in  $P_{Best}$  if c generalizes the corresponding domain value in the record. An empty  $P_c$  is removed.  $Link_c$  is created to link up all  $P_c$ 's for the same c. Also, link  $P_c$  to every  $Link_x$  to which  $P_{Best}$  was previously linked, except for  $Link_{Best}$ . Finally, mark c as "beneficial" if  $R_c$  has more than one class. Recall that  $R_c$  is the set of data records generalized to c.

We emphasize that this is the only operation in the whole algorithm that requires accessing data records. The overhead of maintaining  $Link_x$  is small. For each attribute in  $\cup VID_j$  and each leaf partition on  $Link_{Best}$ , there are at most |child(Best)| "relinkings", or at most  $|\cup VID_j| \times |Link_{Best}| \times |child(Best)|$  "relinkings" in total for applying Best.

**Example 8** Continue with Example 7. Initially, TIPS has only one leaf partition containing all data records and representing the generalized record  $\langle ANY\_Edu, ANY\_Sex, [1-99) \rangle$ . Let the best specialization be  $[1-99) \rightarrow \{[1-37], [37-99]\}$  on  $Work\_Hrs$ . We create two child partitions under the root partition as in Figure 3, and split data records between them. Both child partitions are on  $Link_{ANY\_Edu}$  and  $Link_{ANY\_Sex}$ .  $\cup Cut_i$  is updated into  $\{ANY\_Edu, ANY\_Sex, [1-37], [37-99]\}$ . Suppose that the next best specialization is  $ANY\_Edu \rightarrow \{Secondary, University\}$ , which specializes the two leaf partitions on  $Link_{ANY\_Edu}$ , resulting in the TIPS in Figure 3. ■

A scalable feature of our algorithm is maintaining some statistical information for each candidate x in  $\cup Cut_i$  for updating Score(x) without accessing data records. For each new value c in child(Best) added to  $\cup Cut_i$  in the current iteration, we collect the following count statistics of c while scanning data records in  $P_{Best}$  for updating TIPS:

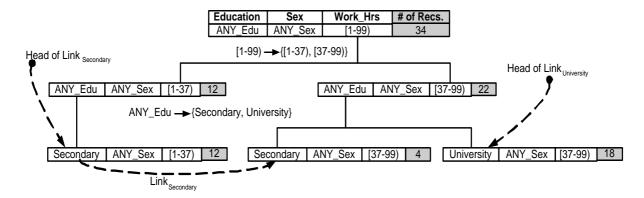

Figure 3. The TIPS data structure

(1)  $|R_c|$ ,  $|R_d|$ ,  $freq(R_c, cls)$ , and  $freq(R_d, cls)$  for computing InfoGain(c), where  $d \in child(c)$  and cls is a class label. Refer to Section 4 for these notations. (2)  $|P_d|$ , where  $P_d$  is a child partition under  $P_c$  as if c is specialized, kept together with the leaf node for  $P_c$ . These information will be used in Section 5.4.

TIPS has several useful properties. (1) All data records in the same leaf partition have the same generalized record although they may have different lower level values. (2) Every data record appears in exactly one leaf partition. (3) Each leaf partition  $P_x$  has exactly one generalized  $vid_j$  on  $VID_j$  and contributes the count  $|P_x|$  towards  $a(vid_j)$ . Later, we use the last property to extract  $a(vid_j)$  from TIPS.

#### **5.4.** Update the Score

This step updates Score(x) for candidates x in  $\cup Cut_i$  to reflect the impact of  $Best \to child(Best)$ . The key to the efficiency of our algorithm is computing Score(x) from the count statistics maintained in Section 5.3 without accessing data records. We update InfoGain(x) and  $A_x(VID_j)$  separately. Note that the updated  $A(VID_j)$  is obtained from  $A_{Best}(VID_j)$ .

#### **5.4.1** Update InfoGain(x)

A quick observation is that InfoGain(x) is not affected by applying  $Best \rightarrow child(Best)$  except that we need to compute InfoGain(c) for each value c in child(Best). InfoGain(c) can be computed while collecting the count statistics for c in Section 5.3.

#### **5.4.2** Update AnonyLoss(x)

Unlike information gain, it is not enough to compute  $A_c(VID_j)$  only for each c in child(Best). Recall that  $A_x(VID_j)$  is the minimum  $a(vid_j)$  after specializing

x. If att(x) and att(Best) are contained in  $VID_j$ , the specialization on Best may affect this minimum, hence,  $A_x(VID_j)$ . Below, we present a data structure, Virtual  $Identifier\ TreeS\ (VITS)$ , to extract  $a(vid_j)$  efficiently from TIPS for updating  $A_x(VID_j)$ .

**Definition 4 (VITS)**  $VIT_j$  for  $VID_j = \{D_1, \ldots, D_w\}$  is a tree of w levels. The level i > 0 represents the generalized values for  $D_i$ . Each root-to-leaf path represents an existing  $vid_j$  on  $VID_j$  in the generalized data, with  $a(vid_j)$  stored at the leaf node. A branch is trimmed if its  $a(vid_j) = 0$ .  $A(VID_j)$  is the minimum  $a(vid_j)$  in  $VIT_j$ .

In other words,  $VIT_j$  provides an index of  $a(vid_j)$  by  $vid_j$ . Unlike TIPS, VITS does not maintain data records. On applying  $Best \to child(Best)$ , we update every  $VIT_j$  such that  $VID_j$  contains att(Best).

Update  $VIT_j$ . For each occurrence of Best in  $VIT_j$ , create a separate branch for each c in child(Best). The procedure in Table 5 computes  $a(vid_j)$  for the newly created  $vid_j$ 's on such branches. The general idea is to loop through each  $P_c$  on  $Link_c$  in TIPS, increment  $a(vid_j)$  by  $|P_c|$ . This step does not access data records because  $|P_c|$  was part of the count statistics of Best. Let r be the number of  $VID_j$  containing att(Best). The number of  $a(vid_j)$  to be computed is at most  $r \times |Link_{Best}| \times |child(Best)|$ .

```
\begin{array}{ll} 1 & \text{Procedure UpdateCounts} \\ 2 & \textbf{for} \ \text{each} \ P_c \in Link_c \ \textbf{do} \\ 3 & \textbf{for} \ \text{each} \ VID_j \ \text{containing} \ att(Best) \ \textbf{do} \\ 4 & a(vid_j) = a(vid_j) + |P_c|, \ \text{where} \\ & vid_j \ \text{is the generalized value on} \ VID_j \ \text{for} \ P_c \\ 5 & \textbf{end for} \\ 6 & \textbf{end for} \end{array}
```

Table 5. Computing  $a(vid_j)$  for new  $vid_j$ 

**Example 9** In Figure 4, the initial  $VIT_1$  and  $VIT_2$  (i.e., left most) have a single path. After applying  $[1-99) \rightarrow \{[1-37), [37-99]\}$ , the vid  $\langle ANY\_Sex, [1-99) \rangle$  in  $VIT_2$  is replaced with two new vids  $\langle ANY\_Sex, [1-37) \rangle$  and  $\langle ANY\_Sex, [37-99) \rangle$ , and  $A(VID_2) = 12$ . Since  $VID_1$  does not include  $Work\_Hrs, VIT_1$  remains unchanged and  $A(VID_1) = 34$ .

After applying the second specialization  $ANY\_Edu \rightarrow \{Secondary, University\}$ ,  $VIT_2$  remains unchanged, and  $A(VID_2) = 12$ . The vid  $<ANY\_Edu,ANY\_Sex>$  in  $VIT_1$  is replaced with two new vids  $<Secondary,ANY\_Sex>$  and  $<University, ANY\_Sex>$ . To compute a(vid) for these new vids, we add  $|P_{Secondary}|$  on  $Link_{Secondary}$  and  $|P_{University}|$  on  $Link_{University}$  (see Figure 3):  $a(<Secondary, ANY\_Sex>) = 0 + 12 + 4 = 16$ , and  $a(<University, ANY\_Sex>) = 0 + 18 = 18$ . So  $A_{ANY\_Edu}(VID_1) = 16$ .  $\blacksquare$ 

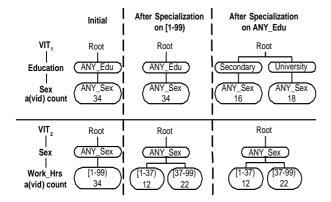

Figure 4. The VITS data structure

Now, we update  $A_x(VID_j)$  for candidates x in  $\cup Cut_i$  in the impact of  $Best \to child(Best)$ . Doing this by specializing x requires accessing data records, hence, is not scalable. We like to compute  $A_x(VID_j)$  using the count statistics maintained for x in  $\cup Cut_i$  without accessing data records.

**Update**  $A_x(VID_j)$ . For a candidate x in  $\cup Cut_i$ , computing  $A_x(VID_j)$  is necessary in two cases. First, x is in child(Best) because  $A_x(VID_j)$  has not been computed for newly added candidates x. Second,  $A_x(VID_j)$  might be affected by the specialization on Best, in which case att(x) and att(Best) must be contained in  $VID_j$ . In both cases, we first compute  $a(vid_j^x)$  for the new  $vid_j^x$ 's created  $as\ if\ x$  is specialized. The procedure is the same as in Table 5 for specializing Best, except that Best is replaced with x and no actual update is performed on  $VIT_j$  and TIPS. Note that the count  $|P_c|$ , where c is in child(x), in the procedure is part of the count statistics maintained for x.

Next, we compare  $a(vid_j^x)$  with  $A(VID_j)$  to determine the minimum, i.e.,  $A_x(VID_j)$ . There are two cases:

Case 1: If no contributing vid of  $A(VID_j)$  (i.e., those vids such that  $a(vid) = A(VID_j)$ ) contains the value x, then such vids remain existing if x is specialized, so  $A_x(VID_j)$  is the minimum of  $A(VID_j)$  and  $a(vid_x^x)$ .

Case 2: If some contributing vid of  $A(VID_j)$  contains the value x, such vid's become new  $vid_j^x$  if x is specialized, so  $A_x(VID_j)$  is the minimum of  $a(vid_i^x)$ .

Finally, if the new  $A_x(VID_j) \ge k_j$ , we keep it with x and mark x as "valid" in the cut.

#### 5.5. Discussion

Each iteration involves two types of work. The first type accesses data records in  $R_{Best}$  for updating TIPS and count statistics in Section 5.3. The second type computes Score(x) (i.e., InfoGain(x) and  $A_x(VID_j)$ ) for the candidates x in  $\cup Cut_i$  without accessing data records in Section 5.4. For a table with m attributes and each taxonomy tree with at most p nodes, the number of such x is at most  $m \times p$ . This computation makes use of the maintained count statistics, rather than accessing data records. In other words, each iteration accesses only the records being specialized.

In the special case that there is only a single VID, each root-to-leaf path in TIPS has represented a vid, and we can store a(vid) directly at the leaf partitions in TIPS without VITS. A single VID was considered in [10, 6] where the VID contains all potentially identifying attributes to be used for linking the table to an external source. Our algorithm is more efficient in this special case.

To focus on main ideas, our current implementation assumes that the compressed table fits in memory. Often, this assumption is valid because the compressed table can be much smaller than the original table. If the compressed table does not fit in the memory, we can store leaf partitions of TIPS on disk if necessary. Favorably, the memory is used to keep only leaf partitions that are smaller than the page size to avoid fragmentation of disk pages. A nice property of TDS is that leaf partitions that cannot be further specialized (i.e., on which there is no candidate specialization) can be discarded, and only some statistics for them needs to be kept. This likely applies to small partitions in memory, therefore, the memory demand is unlikely to build up.

Compared to iteratively generalizing the data bottomup starting from domain values, the top-down specialization is more natural and efficient for handling continuous attributes. To produce a small number of intervals for a continuous attribute, the top-down approach needs only a small number of interval splitting, whereas the bottom-up approach needs many interval merging starting from many domain values. In addition, the top-down approach can discard data records that cannot be further specialized, whereas the bottom-up approach has to keep all data records until the end of computation.

Attribute	Type	Numerical Range	
		# of Leaves	# of Levels
Age (A)	continuous	17 - 90	
Capital-gain (Cg)	continuous	0 - 99999	
Capital-loss (Cl)	continuous	0 - 4356	
Education-num (En)	continuous	1 - 16	
Final-weight (Fw)	continuous	13492 - 1490400	
Hours-per-week (H)	continuous	1 - 99	
Education (E)	categorical	16	5
Martial-status (M)	categorical	7	4
Native-country (N)	categorical	40	5
Occupation (O)	categorical	14	3
Race (Ra)	categorical	5	3
Relationship (Re)	categorical	6	3
Sex (S)	categorical	2	2
Work-class (W)	categorical	8	5

Table 6. Attributes for the Adult data set

## 6. Experimental Evaluation

We have three objectives in this section. (1) Verify if the proposed method, TDS, can generalize a given data set to satisfy a broad range of anonymity requirements without sacrificing significantly the usefulness to classification. (2) Compare TDS with the genetic algorithm presented in Iyengar [6] in terms of both accuracy and efficiency. (3) Evaluate the scalability of TDS on larger data sets. The result of Iyengar [6] was quoted from that paper. All experiments based on TDS were conducted on an Intel Pentium IV 2.6GHz PC with 1GB RAM.

We adopted the publicly available benchmark *Adult* data set from [4]. It has 6 continuous attributes, 8 categorical attributes, and a binary Class column representing two income levels,  $\leq 50 \, \mathrm{K}$  or  $> 50 \, \mathrm{K}$ . Table 6 describes each attribute. After removing records with missing values from the pre-split training and testing sets, we have 30,162 records and 15,060 records for training and testing respectively. This is exactly the same data set as used in [6].

Although the author of [6] has specified taxonomy trees for categorical attributes, we do not agree with the author's groupings. For example, the author grouped *Native-country* according to continents, except Americas. We followed the grouping according to the World Factbook published by CIA<sup>1</sup>. Our taxonomy trees and an executable program of TDS can be obtained from our website<sup>2</sup>. Nevertheless, we did use Iyengar's taxonomy trees in Section 6.2 for comparison purpose.

## 6.1. Data Quality

Our first objective is to evaluate if the proposed TDS preserves the quality for classification while generalizing the data to satisfy various anonymity requirements. We used the C4.5 classifier [8] and Naive Bayesian classifier<sup>3</sup> as classification models. Unless stated otherwise, all 14 attributes were used for building classifiers.

In a typical real life situation, the data provider releases all data records in a single file, leaving the split of training and testing sets to the data miner. Following this practice, we combined the training set and testing set into one set for generalization, and built a classifier using the generalized training set and collected the error using the generalized testing set. This error, called the *anonymity error* and denoted AE, was compared with the *baseline error*, denoted BE, for the unmodified training and testing sets. Note that AE depends on the anonymity requirement. BE is 14.7% for the C4.5 classifier and 18.07% for the Naive Bayesian classifier. AE - BE measures the quality loss due to data generalization.

For the same anonymity threshold k, a single VID is always more restrictive than breaking it into multiple VIDs. For this reason, we first consider the case of single VID. To ensure that generalization is working on attributes that have impacts on classification, the VID contains the top Nattributes ranked by the C4.5 classifier. The top rank attribute is the attribute at the top of the C4.5 decision tree. Then we remove this attribute and repeat this process to determine the rank of other attributes. The top 9 attributes are Cg, A, M, En, Re, H, S, E, O in that order. We specified three anonymity requirements denoted Top5, Top7, and Top9, where the VID contains the top 5, 7, and 9 attributes respectively. The *upper error*, denoted UE, refers to the error on the data with all the attributes in the VID removed (equivalent to generalizing them to the top most ANY). UE-BE measures the impact of the VID on classification.

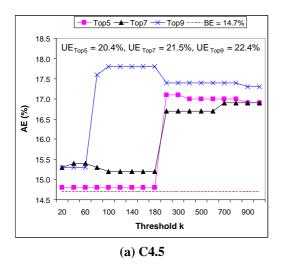

Figure 5a displays AE for the C4.5 classifier with the anonymity threshold  $20 \le k \le 1000$ . Note that k is not spaced linearly. We summarize the analysis for Top7 as follows. First, AE-BE, where BE=14.7%, is less than 2% over the range of anonymity threshold  $20 \le k \le 600$ , and AE is much lower than UE=21.5%. This supports that accurate classification and privacy protection can coexist. Second, AE generally increases as the anonymity threshold k increases, but not monotonically. For example, the error slightly drops when k increases from 60 to 100. This is due to the variation between the training set and testing set and the fact that a better structure may appear in a more general state.

A closer look at the generalized data for Top7 with

<sup>&</sup>lt;sup>1</sup>http://www.cia.gov/cia/publications/factbook/

<sup>&</sup>lt;sup>3</sup>http://magix.fri.uni-lj.si/orange/

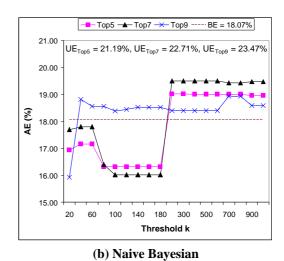

Figure 5. Anonymity error of TDS on TopN

k=500 reveals that among the seven top ranked attributes, three are generalized to a different degree of granularity, and four, namely A (ranked 2nd), Re (ranked 5th), S (ranked 7th), and Cg (ranked 1st), are generalized to the top most value ANY. Even for this drastic generalization, AE has only increased by 2% from BE=14.7%, while the worst case can be UE=21.5%. With the generalization, classification now is performed by the remaining three attributes in the VID and the unmodified but lower ranked attributes. Clearly, this is a different classification structure from what would be found from the unmodified data. As a result, though generalization may eliminate some structures, new structures emerge to help.

Figure 5b displays AE for the Naive Bayesian classifier. Compared to the C4.5 classifier, though BE and UE are higher (which has to do with the classification method, not the generalization), the quality loss due to generalization, AE-BE (note BE=18.07%), is smaller, no more than 1.5% for the range of anonymity threshold  $20 \le k \le 1000$ . This suggests that the information based generalization is also useful to other classification methods such as the Naive Bayesian that do to use the information bias. Another observation is that AE is even lower than BE for the anonymity threshold  $k \le 180$  for Top5 and Top7. This confirms again that the best structure may not appear in the most specialized data. Our approach uses this room to mask sensitive information while preserving classification structures.

Figure 6 shows the generated taxonomy trees for continuous attributes Hours-per-week and Education-num with Top7 and k=60. The splits are very reasonable. For example, in the taxonomy tree of Education-num, the split point at 13 distinguishes whether the person has post-secondary education. If the user does not like these trees, she may modify them or specify her own and subsequently treat

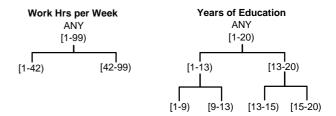

Figure 6. Generated taxonomy trees of *Hours*per-week and *Education-num* 

continuous attributes as categorical attributes with specified taxonomy trees.

Our method took at most 10 seconds for all previous experiments. Out of the 10 seconds, approximately 8 seconds were spent on reading data records from disk and writing the generalized data to disk. The actual processing time for generalizing the data is relatively short.

In an effort to study the effectiveness of multiple VIDs, we compared AE between a multiple VIDs requirement and the *corresponding* single united VID requirement. We randomly generated 30 multiple VID requirements as follows. For each requirement, we first determined the number of VIDs using the uniform distribution U[3,7] (i.e., randomly drawn a number between 3 and 7) and the length of VIDs using U[2,9]. For simplicity, all VIDs in the same requirement have the same length and same threshold k=100. For each VID, we randomly selected some attributes according to the VID length from the 14 attributes. A repeating VID was discarded. For example, a requirement of 3 VIDs and length 2 is

$$\{ < \{A, En\}, k >, < \{A, R\}, k >, < \{S, H\}, k > \},$$

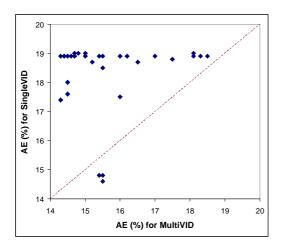

Figure 7. Single VID vs MultiVID (k=100)

and the corresponding single VID requirement is  $\{ \langle \{A, En, R, S, H\}, k \rangle \}.$ 

In Figure 7, each data point represents the AE of a multiple VID requirement, denoted MultiVID, and the AE of the corresponding single VID requirement, denoted Single-VID. The C4.5 classifier was used. Most data points appear at the upper left corner of the diagonal, suggesting that MultiVID generally yields lower AE than its corresponding SingleVID. This verifies the effectiveness of multiple VIDs to avoid unnecessary generalization and improve data quality.

## 6.2. Comparing with Genetic Algorithm

Iyengar [6] presented a genetic algorithm solution. See Section 2 for a brief description or [6] for the details. Experiments in this section were customized to conduct a fair comparison with his results. We used the same Adult data set, same attributes, and the same anonymity requirement as specified in [6]:

$$GA = {A, W, E, M, O, Ra, S, N}, k >.$$

We obtained the taxonomy trees from the author, except for the continuous attribute A. Following Iyengar's procedure, all attributes not in GA were removed and were not used to produce BE, AE, and UE in this experiment, and all errors were based on the 10-fold cross validation and the C4.5 classifier. For each fold, we first generalized the training data and then applied the generalization to the testing data.

Figure 8 compares AE of TDS with the errors reported for two methods in [6], Loss Metric (LM) and Classification Metric (CM), for  $10 \le k \le 500$ . TDS outperformed LM, especially for  $k \ge 100$ , but performed only slightly better than CM. TDS continued to perform well from k = 500 to k = 1000, for which no result was reported for LM and CM

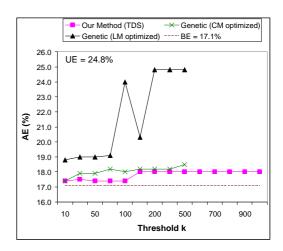

Figure 8. Comparing with genetic algorithm

in [6]. This analysis shows that our method is at least comparable to Iyengar's genetic algorithm in terms of accuracy. However, our method took only 7 seconds to generalize the data, including reading data records from disk and writing the generalized data to disk. Iyengar [6] reported that his method requires 18 hours to transform this data, which has about only 30K data records. Clearly, the genetic algorithm is not scalable.

#### 6.3. Efficiency and Scalability

This experiment evaluates the scalability of TDS by blowing up the size of the Adult data set. First, we combined the training and testing sets, giving 45,222 records. For each original record r in the combined set, we created  $\alpha-1$  "variations" of r, where  $\alpha>1$  is the blowup scale. For each variation of r, we randomly selected q attributes from  $\cup VID_j$ , where q has the uniform distribution  $U[1,|\cup VID_j|]$ , i.e., randomly drawn between 1 and the number of attributes in VIDs, and replaced the values on the selected attributes with values randomly drawn from the domain of the attributes. Together with all original records, the enlarged data set has  $\alpha\times45,222$  records. In order to provide a more precise evaluation, the runtime reported in this section excludes the time for loading data records from disk and the time for writing the generalized data to disk.

Figure 9 depicts the runtime of TDS for 200K to 1M data records and the anonymity threshold k=50 based on two types of anonymity requirements. AllAttVID refers to the single VID having all 14 attributes. This is one of the most time consuming settings because of the largest number of candidate specializations to consider at each iteration. For TDS, the small anonymity threshold of k=50 requires more iterations to reach a solution, hence more runtime,

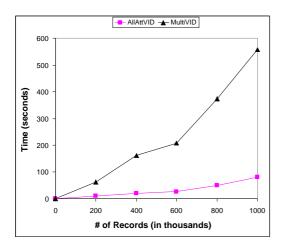

Figure 9. Scalability vs # of records (k=50)

than a larger threshold. TDS takes approximately 80 seconds to transform 1M records.

In Figure 9, MultiVID refers to the average runtime over the 30 random multiple VID requirements in Section 6.1 with k=50. Compared to AllAttVID, TDS becomes less efficient for handling multiple VIDs for two reasons. First, an anonymity requirement on multiple VIDs is a less restrictive constraint than the single VID anonymity requirement containing all attributes; therefore, TDS has to perform more specializations before violating the anonymity requirement. Moreover, TDS needs to create one VIT for each VID and maintains a(vid) in VITS. The increase is roughly by a factor proportional to the number of VIDs in an anonymity requirement.

## **6.4. Summary**

Our experiments verified several claims about the proposed TDS method. First, TDS generalizes a given table to satisfy a broad range of anonymity requirements without sacrificing significantly the usefulness to classification. Second, while producing a comparable accuracy, TDS is much more efficient than previously reported approaches, particularly, the genetic algorithm in [6]. Third, TDS scales well with large data sets and complex anonymity requirements. These performances together with the features discussed in Section 1 make TDS a practical technique for privacy protection while sharing information.

## 7. Conclusions

We considered the problem of protecting individual privacy while releasing person-specific data for classification modelling. Our approach is based on two observations: sen-

sitive information tends to be overly specific, thus of less utility, to classification; even if masking sensitive information eliminates some useful structures, alternative structures in the data emerge to help. We presented a top-down approach to iteratively specialize the data from a general state into a special state, guided by maximizing the information utility and minimizing the privacy specificity. This top-down approach serves a natural and efficient structure for handling categorical and continuous attributes and multiple anonymity requirements. Experiments showed that our approach effectively preserves both information utility and individual privacy and scales well for large data sets.
